## Abstract

This paper presents a framework for the quantitative analysis of individual income dynamics, mobility and welfare. Individual income is assumed to follow a stochastic process with two (unobserved) components, an i.i.d. component representing measurement error or transitory income shocks and an AR(1) component representing persistent changes in income. We show how the parameters of the income process can be estimated using repeated cross-sectional data with a short panel dimension, and use a simple consumption-saving model to provide a transparent link between income process, mobility, and welfare. The empirical application of our framework using data on individual incomes from Mexico provides striking results. Much of measured income mobility is driven by measurement error or transitory income shocks and therefore (almost) welfare-neutral. A smaller part of measured income mobility is due to either welfare-reducing income risk or welfare-enhancing catching-up of low-income individuals with high-income individuals, both of which have economically significant effects on social welfare. Decomposing mobility into its fundamental components is thus seen to be crucial from the standpoint of welfare evaluation.

\*We are grateful to seminar participants at Columbia, Harvard and Pennsylvania State University for many useful comments. Particular thanks to Francois Bourguignon, Francisco Ferreira, Gary Fields, and the other participants at the World Bank/Universitat Autònoma de Barcelona Workshop on Mobility for very helpful discussions. Our appreciation to Edwin Goni and Mauricio Sarrias for inspired research assistance. This work was partially supported by the Regional Studies Program of the Office of the Chief Economist for Latin America and the World Bank Research Support Budget.

# I. Introduction

Individual income dynamics characterize society in important ways. The degree to which individuals move across different sections of the income distribution is often summarized by one parameter, income mobility. Indeed, income mobility is probably the single most important indicator of individual income *dynamics* used in public policy discussions, in particular in the analysis of income data of developing countries.<sup>1</sup> Income mobility is important as it informs us about the opportunities afforded by society to escape one's origins. At the same time, mobility may also be driven by variability in incomes that reflect the risk to which individuals are exposed in the economy.

In this paper, we develop an analytical framework for the estimation and welfare-theoretic evaluation of individual income dynamics that takes into account these different drivers of income mobility. Our approach only requires repeated cross-sectional data with a short panel dimension, which makes it particularly useful for applications to developing country data sets. We provide an application of our framework using individual income data from Mexico that yields striking results: Much of measured income mobility is driven by measurement error or transitory income shocks and therefore (almost) welfare-neutral. A smaller part of measured income mobility is due to either welfare-reducing income risk or welfare-enhancing catching-up of low-income individuals with high-income individuals, both of which have economically significant effects on social welfare. Decomposing mobility into its fundamental components is thus crucial from the standpoint of welfare evaluation.

The literature on income mobility has often focused on two important questions: the quantitative/empirical measurement of the extent and nature of the change in individual incomes and, separately, the social-welfare-theoretic evaluations of such changes.<sup>2</sup> Two

---

<sup>1</sup>See, for example, the large number of mobility studies published by the World Bank, most recently their flagship publication in 2012, "Economic Mobility and the Rise of the Middle Class," which focuses on Latin America.

<sup>2</sup>For the former, see Lillard and Willis (1978), Shorrocks (1978b), Geweke, Marshal and Zarkin (1986), Conlisk (1990) and Fields and Ok (1996). For the latter, see, Atkinson (1983), Markandya (1982, 1984), Atkinson, Bourguignon and Morrison (1992), Dardononi (1993), and Gottschalk and Spolaore (2002). Additionally, the discussion over suitable social (income) mobility measures (indices), which may be used to

methodological issues have arisen in this area. First, the parametric formulations used in the measurement of income changes are not easily used as inputs to the quantitative welfare-theoretic analysis, thereby constituting a problematic gap between these two literatures. Furthermore, as the literature has often pointed out, the measurement of dynamic income changes is itself confronted by (at least) the following two problems. First, income data are subject to measurement error and, second, a significant proportion of the observed income changes may be simply temporary in nature - resulting, typically, in an overestimation of the relevant mobility in income.<sup>3</sup> This is also important from the perspective of welfare analysis, as measurement error has no effect on workers' welfare and transitory shocks to income are perhaps easily smoothed out, resulting in very small welfare effects. In addition, welfare analysis is confronted by an additional challenge. Since individual utility is postulated as taking consumption rather than income as its argument, its direct valuation requires reliable data on individual consumption levels, which are often unavailable for developing countries. To use the more easily available data on incomes, a theoretical framework is required that translates the estimated income dynamics into consumption changes taking into account the institutional constraints individual agents face.

In this paper, we develop a tractable analytical framework to study income mobility that provides a close link between the welfare theory and the empirical methodology used in the measurement of the income dynamics, thereby helping to bridge the gap between these literatures. At the same time, this framework overcomes many of the methodological problems that we have just discussed. We note, at the outset, that our focus is on income mobility within individual lifetimes (intra-generational mobility). Our approach consists of two steps.

In a first step, we follow a large empirical literature on individual income dynamics and postulate a stochastic income process that is highly parameterized, but sufficiently

---

evaluate mobility given the pattern of individual income changes in society, constitutes a very well researched area that has generated a number of important contributions in recent years. See Fields and Ok (1999) for a survey discussion.

<sup>3</sup>See, for example, Lillard and Willis (1978) Solon (2001), Luttmer (2002), Fields et al (2003), Glewwe (2004), and Antman and McKenzie (2007).

elaborate to distinguish between changes in income resulting from trend growth and other predictable factors and changes in income that are unpredictable.<sup>4</sup> The unpredictable part of income change, in turn, has two components, one first degree autoregressive (AR(1)) component reflecting persistent shocks to income and another component that is i.i.d and captures transitory shocks and measurement error in the income data. We show how income mobility, measured in relation to the correlation of incomes over time,<sup>5</sup> relates to the various parameters of the underlying income process. Further, we show how the parameters of the income process can be estimated using an econometric approach that exploits both the longitudinal and repeated cross-sectional features of income data, and apply our estimation strategy to individual income data from Mexico (Sections III-V).<sup>6</sup> Our econometric approach is particularly suited for the application to Mexico and other developing countries, where data sets with a long panel dimension do not exist, but repeated cross-sectional observations with a very short panel dimension (rotating panel) are available.

In a second step, we follow the large literature on consumption-saving models to provide a link between income dynamics, consumption, and welfare.<sup>7</sup> Specifically, we present a tractable framework that has the merit of linking income dynamics, income mobility and social welfare in a simple and transparent manner.<sup>8</sup> This approach allows us to provide a

---

<sup>4</sup>See, for example, Baker and Solon (2003) and Meghir and Pistaferri (2011) for a detailed discussion of the literature.

<sup>5</sup>Specifically, we use a quite basic and familiar measure, the Hart Index, which is the complement of the correlation between the logarithm of incomes over times (see Hart (1981) and Shorrocks (1993)). As Fields and Ok (1996) discuss, however, the literature has recently made important advances in studying the “multi-faceted concept” of mobility and a number of different theoretical measures, each capturing a different aspect of mobility have been introduced. We have no contribution to make to this discussion and simply use the Hart Index as our basic measure of mobility.

<sup>6</sup>For an interesting exercise which compares results on poverty vulnerability (the propensity to move into poverty) obtained using panel data on incomes with those obtained from repeated cross-sections instead and finds that model parameters recovered from pseudo-panels approximate reasonably well those estimated directly from a true panel, see Bourguignon, Goh and Kim (2006).

<sup>7</sup>See Deaton (1991) and Carroll (1997) for the basic partial equilibrium model and Huggett (1993) and Aiyagari (1994) for the seminal applications to general equilibrium analysis. See Heathcote, Storesletten, and Violante (2009) for a recent survey.

<sup>8</sup>More precisely, we base our welfare analysis on the tractable framework of Constantinides and Duffie (1996) and Krebs (2007), who emphasize the effect of (exogenous) labor income risk on consumption and welfare. Angeletos (2007) presents a tractable incomplete-market model that focuses on entrepreneurial (investment) risk. Heathcote, Storesletten, and Violante (2008) develop an analytical framework that allows

clear analytical and quantitative discussion of these interrelated concepts, and specifically the role of income variability. We discuss in detail how different determinants of measured income mobility may have quite different implications for welfare. Specifically, we show that the auto-correlation coefficient of the AR(1) process (the catching-up parameter) measures “good mobility” in the sense that a reduction in this parameter increases both mobility and welfare. In contrast, social welfare is (almost) unaffected by measurement error or transitory income shocks even though mobility increases with the variance of the i.i.d. component of labor income. Finally, the variance of persistent income shocks (income risk) increases mobility, but decreases social welfare. This implies that two societies with the same initial distribution of income and the same level of measured income mobility and aggregate growth may experience quite different social welfare changes depending upon the different combinations of the underlying income parameters.

We present a quantitative implementation of our framework that underscores the importance of decomposing income dynamics into its components, as we have discussed. Specifically, an application using data on individual incomes from Mexico yields striking results. Most of measured income mobility is driven by measurement error or transitory income shocks and therefore (almost) welfare-neutral, and only a small part of measured income mobility is due to either welfare-reducing income risk or welfare-enhancing catching-up of low-income individuals with high-income individuals. However, despite the small mobility effects, (idiosyncratic) persistent income risk has significant negative effects on social welfare – eliminating or insuring it would generate welfare gains that are equivalent to an increase in lifetime consumption by about 10 percent even if workers are only moderately risk-averse (log-utility).<sup>9</sup> Eliminating the catch-up of low income individuals with high income individuals yields a loss in social welfare of similar magnitude. Decomposing mobility into its fundamental components is thus seen to be crucial from the standpoint of welfare evaluation.

---

for partial insurance and endogenous labor supply.

<sup>9</sup>In comparison, for the same preference parameters, Lucas (2003) computes welfare cost of aggregate consumption fluctuations in the US that are two orders of magnitude smaller. Thus, even though our estimates of persistent income risk seem small when measured mobility is the yardstick, their welfare effect is large indeed.

In sum, in this paper we make three contributions. First, we present a highly tractable framework that provides a transparent link between income dynamics, mobility, and welfare. Second, we show how the parameters of the income process can be estimated using repeated cross-sectional data with a short panel dimension, which permits the application of our approach to developing countries. Third, we apply our approach to individual income data from Mexico and show the importance of decomposing income mobility into its fundamental components.

We conclude the introduction with a general remark. In this paper, we use a highly tractable model to provide a link between income dynamics and consumption and welfare. The simplicity of our approach has the advantage of clarifying the basic channels that we like to emphasize in this paper. However, it has the disadvantage of leaving out some additional channels that are potentially important. For example, we use an exchange economy so that any effect of income risk on physical capital accumulation (Aiyagari, 1994, and Angeletos, 2007) or human capital accumulation (Krebs, 2003) are ruled out by assumption. Further, we focus on households with little financial wealth implying very strong effects of permanent labor income shocks on consumption. In contrast, for wealthy US households the evidence indicates that the effect of permanent income shocks on consumption is substantially less than one-to-one (Blundell, Pistaferri, and Peston 2008). Moreover, endogenous labor supply has been shown to provide additional insurance (Heathcote et al, 2008), and risk sharing among friends and family members is an important issue in the context of developing countries. Finally, we have adopted the time-honored assumptions of time-additive expected utility preferences.<sup>10</sup> Gottschalk and Spolaore (2002) analyze mobility and welfare in a setting with more general preferences that do not obey the independence axiom. Extending our analysis to models that allow for non-expected utility preferences and additional insurance channels are important topics for future research.

---

<sup>10</sup>We also assume that the one-period utility function is logarithmic, but our analysis can easily be extended to the general case of CRRA-utility functions.

## II. Income and Mobility

### II.1. Income Process

Consider a large number of workers indexed by  $i$ . For notational ease, we focus on one cohort of workers who enter the labor market for the first time in period  $t = 0$  so that  $t = 0, 1, \dots$  stands for both calendar time and age (experience) of the worker. Let  $y_{it}$  stand for the labor income of worker  $i$  in period  $t$ . Following a longstanding tradition in micro-econometrics, we postulate that the log of  $y_{it}$  is a random variable that is the sum of two components, a persistent component,  $\omega_{it}$ , and a transitory component,  $\eta_{it}$ .<sup>11</sup> In addition, we set the mean of  $\ln y_{it}$  to  $\mu$ . In short, we have:

$$\log y_{it} = \omega_{it} + \eta_{it} + \mu . \quad (1)$$

The persistent component,  $\omega_{it}$ , follows an AR(1) process

$$\omega_{i,t+1} = \rho\omega_{it} + \epsilon_{i,t+1} , \quad (2)$$

where  $\rho$  is a parameter measuring the persistence of shocks. The term  $\epsilon$  denotes a stochastic innovation to labor income, which we assume to be i.i.d. over time and across individuals. We further assume that the transitory component of labor income,  $\eta_{it}$ , is i.i.d. over time and across individuals. Moreover,  $\eta_{it}$  and  $\epsilon_{i,t+n}$  are uncorrelated for all  $t$  and  $n$ . All random variables are normally distributed so that labor income is log-normally distributed. More specifically, we assume that  $\epsilon_{it} \sim N(0, \sigma_\epsilon^2)$ ,  $\eta_{it} \sim N(0, \sigma_\eta^2)$ , and  $\omega_{i0} \sim N(0, \sigma_{\omega_0}^2)$ .

Equations (1) and (2) together imply that:

$$\ln y_{it} = \rho^t \omega_{i0} + \sum_{n=0}^{t-1} \rho^{t-n-1} \epsilon_{i,n+1} + \eta_{it} + \mu . \quad (3)$$

Thus, labor income in period  $t$  is determined by initial condition,  $\omega_0$ , and stochastic changes, the latter being represented by the transitory shocks,  $\eta$ , and permanent shocks,  $\epsilon$ . From (3)

---

<sup>11</sup>See, for example, Baker and Solon (2003) and Meghir and Pistaferri (2011) for a detailed discussion of the literature. In contrast to some papers in the literature (Gottschalk and Moffitt, 1994, and Carroll and Samwick, 1997), we do not impose the random walk restriction on the persistent component of labor income.

and our assumptions about  $\epsilon$ ,  $\eta$ , and  $\omega_0$  it follows that expected labor income is  $E[\ln y_{it}] = \mu$  and labor income uncertainty before  $\omega_{i0}$  is known is given by

$$\text{var}[\ln y_{it}] = \begin{cases} \rho^{2t} \sigma_{\omega_0}^2 + \sigma_{\eta}^2 + \frac{1-\rho^{2t}}{1-\rho^2} \sigma_{\epsilon}^2 & \text{if } \rho \neq 1 \\ \sigma_{\omega_0}^2 + \sigma_{\eta}^2 + t \sigma_{\epsilon}^2 & \text{if } \rho = 1 \end{cases}. \quad (4)$$

As we have mentioned earlier, our study examines income mobility within individual lifetimes, i.e., intra-generational income mobility.<sup>12</sup> From (2), the parameter  $\rho$  measures persistency of income and thus  $(1-\rho)$  measures the extent to which individuals with low levels of income “initially” will catch up with individuals with high income. In our context, the “initial” period corresponds to the time of entry into the work force after the completion of formal education. Since labor income may vary initially for equivalent individuals, catching-up in this context measures the extent to which individuals with initially low incomes catch up to those with initially high incomes.<sup>13</sup> In the terminology of the growth literature, it measures convergence.<sup>14</sup>

## II.2. Mobility

As noted in the introduction, our empirical measure of income mobility between 0 and  $t$ , which we denote by  $m_t$ , is the Hart index, defined as the complement of the correlation in (log) incomes at 0 and  $t$  (see Shorrocks (1993)):

$$\begin{aligned} m_t &= 1 - \text{corr}(\ln y_{i0}, \ln y_{it}) \\ &= 1 - \frac{\text{cov}(\ln y_{i0}, \ln y_{it})}{\sigma_{\ln y_{i0}} \sigma_{\ln y_{it}}}, \end{aligned} \quad (5)$$

---

<sup>12</sup>For recent work on intra-generational mobility, see Antman and McKenzie (2007), Cuesta and Pizzolitto (2010), Dang et. al. (2011), and Cruces et. al (2011).

<sup>13</sup>In this theoretical section, our discussion relates to initial income differences and subsequent mobility between ex-ante identical individuals. In our discussion of empirical methodology and in our empirical application to Mexican data, we will study mobility between observationally equivalent individuals. That is to say, we examine income differences and mobility in residual income after conditioning for the standard determinants of income such as education and experience.

<sup>14</sup>To see this, suppose  $\rho < 1$ . In this case, we have convergence towards the “steady state”:  $E[\ln y_{it} | \omega_{i0}] \rightarrow \mu$ . Let  $\Delta_0 = \ln y_{i0} - \bar{d}$  be the initial distance from the steady state and  $\Delta_t = \ln y_{it} - \bar{d}$  be the distance in period  $t$ . We can then define the time,  $T$ , it takes to get halfway towards the steady state, which is simply the solution to  $\Delta_T / \Delta_0 = 1/2$ . Using the expression for  $\Delta_T$  and  $\Delta_0$ , it is straightforward to see that  $T$  is increasing in  $\rho$  for  $\rho < 1$ , that is, an increase in  $\rho$  reduces the speed of convergence.

where we have used the notation  $\sigma_{\ln y_{i0}} = \sqrt{\text{var}[\ln y_{i0}]}$  and  $\sigma_{\ln y_{it}} = \sqrt{\text{var}[\ln y_{it}]}$ . Using our income specification from the previous section, we find the following expression for the co-variance:

$$\begin{aligned} \text{cov}(\ln y_{i0}, \ln y_{it}) &= \text{cov}(\omega_{i0} + \eta_{i0}, \rho^t \omega_{i0} + \sum_{n=0}^{t-1} \rho^{t-n-1} \epsilon_{i,n+1} + \eta_{it} + \mu) \\ &= \rho^t \sigma_{\omega_0}^2 \end{aligned} \quad (6)$$

Using (3) and (6), we find the following expression for income mobility:<sup>15</sup>

$$m_t = \begin{cases} 1 - \frac{\rho^t \sigma_{\omega_0}^2}{\sqrt{\sigma_{\omega_0}^2 + \sigma_{\eta}^2} \sqrt{\rho^{2t} \sigma_{\omega_0}^2 + \sigma_{\eta}^2 + \frac{1-\rho^{2t}}{1-\rho^2} \sigma_{\epsilon}^2}} & \text{if } \rho \neq 1 \\ 1 - \frac{\sigma_{\omega_0}^2}{\sqrt{\sigma_{\omega_0}^2 + \sigma_{\eta}^2} \sqrt{\sigma_{\omega_0}^2 + \sigma_{\eta}^2 + t \sigma_{\epsilon}^2}} & \text{if } \rho = 1 \end{cases} . \quad (7)$$

Equation (7) defines income mobility as a function of the parameters of interest,  $\sigma_{\epsilon}^2$ ,  $\sigma_{\eta}^2$ , and  $\rho$ . It is straightforward to show that mobility is increasing in the volatility parameters  $\sigma_{\epsilon}^2$  and  $\sigma_{\eta}^2$ . This is intuitive as an increase in the variance of income shocks increases the variability of individual incomes, lowering the correlation between incomes across time, thus increasing mobility.

Importantly, income mobility is decreasing in  $\rho$  if either  $t$  is small and  $\sigma_{\omega_0}^2 < \sigma_{\eta}^2 + \sigma_{\epsilon}^2$  or  $t$  is large and  $\sigma_{\omega_0}^2 < \sigma_{\epsilon}^2 / (1 - \rho^2)$ :

$$\frac{\partial m_t}{\partial \sigma_{\epsilon}^2} > 0 \quad , \quad \frac{\partial m_t}{\partial \sigma_{\eta}^2} > 0 \quad , \quad \frac{\partial m_t}{\partial \rho} < 0 . \quad (8)$$

Intuitively, any increase in  $\rho$  increases income persistence, reducing the catching-up effect and therefore reducing mobility. Note that both conditions  $\sigma_{\omega_0}^2 < \sigma_{\eta}^2 + \sigma_{\epsilon}^2$  and  $\sigma_{\omega_0}^2 < \sigma_{\epsilon}^2 / (1 - \rho^2)$  are satisfied in our empirical application (see section V).

---

<sup>15</sup>For  $\rho < 1$ , the  $\omega$ -process has a stationary distribution. If we choose as initial distribution this stationary distribution, the  $\omega$ -process becomes stationary with  $\sigma_{\omega_t}^2 = \sigma_{\omega_0}^2 = \sigma_{\epsilon}^2 / (1 - \rho^2)$ . In this case the mobility expression (7) reduces to  $m_t = 1 - \rho^t / (1 + \sigma_{\eta}^2 / \sigma_{\epsilon}^2)$ .

### III. Econometric Implementation

The discussion in the preceding sections has described how the different parameters of the income process ( $\sigma_{\omega_0}^2$ ,  $\sigma_{\epsilon}^2$ ,  $\sigma_{\eta}^2$  and  $\rho$ ) affect mobility. To get to a quantitative assessment of these linkages, we turn next to the methodology and data used to estimate these parameters.

#### III.1. Estimation

We continue to assume that log labor income,  $\ln y_{it}$ , is specified as in (1). We further assume that the deterministic mean component,  $\mu$ , depends on  $x_{it} = (x'_{it}, z_{it})$ , where  $z_{it}$  denotes the age of worker  $i$  in year  $t$  and  $x'_{it}$  is vector of observable individual characteristics beyond age (education, education<sup>2</sup>, gender). We also make the functional form assumption  $\mu_t(x'_{it}, z_{it}) = \lambda_t + \lambda(x') \cdot x'_{it} + \sum_z \lambda(z)\delta(z_{it})$ , where  $\lambda_t$  is a constant that varies by calendar time period (thus absorbing the effects of macroeconomic factors such as aggregate productivity growth and aggregate economic fluctuations on income),  $\lambda(x')$  is a vector of coefficients for the vector of worker characteristics  $x'$ , and  $\delta(z_{it})$  are age-dummies. Thus, log labor income can be written as:

$$\begin{aligned} \ln y_{it} &= \lambda_t + \lambda(x') \cdot x_{it} + \sum_z \lambda(z)\delta(z_{it}) + v_{it} & (1') \\ v_{it} &= \omega_{it} + \eta_{it}. \end{aligned}$$

Equation (1') resembles a typical Mincer specification for labor income for which the residual,  $v_{it}$ , is the sum of two unobserved stochastic components,  $\omega_{it}$  and  $\eta_{it}$ . As in Carroll and Samwick (1997), we first use equation (1') to estimate the residuals  $v_{it}$  and then use these estimated residuals to estimate, in a second step, the parameters of interest. As noted above, this implies, importantly, that our mobility measure relates to residual income  $v$  rather than unconditional income  $\ln y$ .

For notational simplicity, assume that all individuals  $i$  “are born” in period  $t = 0$ , so that  $t$  and  $z$  simultaneously stand for age of the individual and calendar time. Equations (1) and (2) which describe our labor income process imply that the change in residual income

variance with age is given by:

$$\begin{aligned} Var[v_{iz}] &= var[(\omega_{iz} + \eta_{iz})] \\ &= \sigma_{\eta}^2 + \rho^{2z}\sigma_{\omega_0}^2 + \frac{1 - \rho^{2z}}{1 - \rho^2}\sigma_{\epsilon}^2 \end{aligned} \quad (4')$$

(4') links the changes in cross sectional residual income variances over for any age cohort  $z$  with our parameters of interest. Unfortunately, however, (4') is not sufficient to separately identify  $\sigma_{\omega_0}^2$  and  $\sigma_{\epsilon}^2$  since, as can be seen from the expression on the right hand side, both evolve at the same rate with  $z$ . We therefore also use the covariance restriction,

$$\begin{aligned} cov(v_{iz}, v_{i,z+1}) &= cov((\omega_{iz} + \eta_{iz}), (\omega_{i,z+1} + \eta_{i,z+1})) \\ &= \rho^{2z+1}\sigma_{\omega_0}^2 + \frac{1 - \rho^{2z}}{1 - \rho^2}\rho\sigma_{\epsilon}^2 \end{aligned} \quad (6')$$

to achieve identification of all four parameters. Notice that (4') requires, on the left hand side, estimates of the cross-sectional variance of residual income for each age group  $z$ , while (6') requires that we use the panel dimension of our data set to estimate the covariances in individuals' residual incomes  $v_{iz}$  over time. Thus, our estimation strategy exploits both the panel dimension and the repeated cross sections available in the data set. As in Carroll and Samwick (1997), we use residual income data at the individual level to obtain unbiased estimators of the terms on the left hand side of (4') and (6'). Specifically,  $v_{iz}^2$  and  $v_{iz}v_{i,z+1}$  serve as individual level "observations" of the variance and covariance terms on the left hand sides of (4') and (6') respectively. We estimate our system of two equations ((4') and (6')) using a simultaneous, non-linear, seemingly unrelated regressions model (NLSUR) (as described in Gallant, 1975 and Amemiya, 1983). This permits the estimation of the two non-linear equations, with the cross-equation restrictions implied by the common parameters, simultaneously and achieves additional estimation efficiency by combining information from both equations (Davidson & MacKinnon, 2004).<sup>16</sup>

---

<sup>16</sup>See also Davidson and MacKinnon (2004) for a thorough discussion of the asymptotic equivalence between estimates obtained using a non-linear-least-squares methodology and the generalized method of moments.

## IV. Data

Using the estimation methodology described in the preceding section, we estimate income mobility parameters using individual income data from Mexico. Specifically, the individual income data are taken from the Encuesta Nacional de Empleo Urbano (ENEU, Mexican National Urban Employment Survey) which was conducted by the Instituto Nacional de Estadística, Geografía e Informática (INEGI, National Institute of Statistics, Geography and Information), the primary statistical agency in Mexico, and the Secretaría del Trabajo y Previsión Social (STPS, Secretariat of Labor and Social Security), Mexico's Labor Ministry.

Until recently, the ENEU was the primary survey instrument for collecting earnings and employment data in Mexico. The survey is sampled to be representative geographically and by social strata (see INEGI 2000). The basic sampling unit is the dwelling. Demographic information is collected on the household (households) occupying each dwelling. Subsequently, an employment questionnaire is administered for each individual aged 12 and above in the household on position in the household, level of education (years of schooling), age and sex as well as standard measures related to participation in the labor market: occupation, hours worked, employment conditions, search and earnings. Importantly, the ENEU is constructed as a rotating panel, where individuals are surveyed every quarter for a total of five quarters.<sup>17</sup> Worker earnings include overall earnings in the individual's principal occupation from fixed salary payments, hourly or daily wages, piece-meal work, commissions, tips and self employment earnings. The ENEU, in its modern form, has employed a consistent survey instrument from 1987 to 2004; it is thus one of very few long-running surveys with a panel dimension in the developing world. In our study, we are able to use this 18 year span comprising a total of 72 quarters of data.<sup>18</sup>

---

<sup>17</sup>In each round of the rotating panel, the questionnaire records absent members, adds any new members who have joined the household, and records any changes in schooling that have taken place. If none of the original group of household members is found to be living in the dwelling unit in the follow-up survey, the household is recorded as a new household. The interviewers do not track households that move, so they leave the panel. Rates of attrition are comparable to other developing countries (See Antman and McKenzie, 2007).

<sup>18</sup>Since 2004, the ENEU has been replaced by the Encuesta Nacional de Ocupación y Empleo (ENOE,

We note that while the ENEU survey records employment information on all members of the household above 12 years old, for younger workers employment is generally transient and time is often divided among schooling, unpaid support to the household and paid work. Similarly, much later in life, work again becomes more transient. In our analysis, we focus on individuals between the ages 20 and 65.

## V. Results

As discussed in the previous section, our estimation methodology proceeds in two steps. As in Carroll and Samwick (1997), we first use individual data to estimate a Mincer earnings regression. In a second step, the residuals from the Mincer regression are used to estimate income mobility parameters using (4') and (6'). Table 2 reports the estimates from the first stage earnings regression using the ENEU data described in the preceding section. Our estimates are consistent with earlier findings in the literature. Specifically, earnings increase, but at a decreasing rate, with education. Further, earnings increase with potential experience (age) up until the age of 44 after which they decrease again. Males appear to earn 31 percent more than women, conditional on the other covariates.<sup>19</sup>

We use next the residuals from the earnings regression,  $v_{it}$ , to construct individual level “observations” of income variances  $v_{it}^2$  and covariances  $v_{it}v_{i,t+1}$ ,<sup>20</sup> that are to be used on the left hand side of equations (4') and (6') to estimate the income mobility parameters. The age profile of the constructed variance and covariance measures are indicated in Figures 1 and 2, which are generated by regressing the two variables respectively on a complete set of age and time dummies and then plotting the former against age (see Deaton and Paxson, 1994, for a similar exercise). Consistent with equations (4') and (6'), the accumulation of persistent shocks,  $\sigma_\epsilon^2$ , as age increases, gives both relationships an upward slope, albeit at

---

Survey of Occupation and Employment) in 2005. Unfortunately, however, the ENOE instrument differs from ENEU in important ways that make it impossible to match the surveys with confidence.

<sup>19</sup>For robustness we have also run alternate earnings specifications, allowing for both more and less temporal variation, by allowing all parameters to vary in each time period, and separately by constraining even the constant to be invariant across periods (unlike in the specification reported on in Table 2, which includes year fixed effects). The results do not change appreciably.

<sup>20</sup>Note that  $v_{t+1}$  denotes individual  $i$ 's residual one year (four quarters) after  $t$

rates differing by a factor of  $\rho$ .

Estimation results from the joint estimation of (4') and (6'), as described in the previous section, yield the parameter estimates listed in Table 3. The first column presents the results using the full sample, while the second column provides results obtained using data from just those households that enter the sample in the first quarter of each year. Our estimates of the income mobility parameters are also in line with those obtained previously in the literature. The autoregressive component,  $\rho$ , is estimated to be 0.977, which suggests that persistent shocks to income experienced by any individual  $i$  will indeed last a long time. The estimated variance of transitory shocks to income,  $\sigma_\eta^2 = 0.202$ , is significantly larger than the variance of persistent shocks to income,  $\sigma_\epsilon^2 = 0.015$ . This is not surprising given that the  $\eta$ -term in our specification also captures measurement error in income, which we expect to be quite large in our data set.<sup>21</sup> Finally, the estimated variance in initial incomes  $\sigma_{\omega_0}^2 = 0.104$ . As the results in the second column indicate, the estimates are not appreciably different with the restricted sample of households who enter the survey in just the first quarter of each year.

Given our estimates of the income parameters, we can use expressions (7) to analyze mobility patterns. In particular, we can compute how much the individual parameters contribute to overall mobility. Table 4 shows that mobility in residual income across 1 year is 0.67 and it increases as the span of measurement increases to 10 years (0.76) and 25 years (0.84). The reasons behind the surprisingly high 1 year mobility level, and relatively modest increases thereafter, become clearer in the next rows which set to zero each of the key parameters and calculate the resulting change in mobility. Notice, first, that 1-year mobility falls by a full 90 percent if we set  $\sigma_\eta^2 = 0$  – no transitory shocks or measurement error. As we have noted earlier, measurement error should not enter welfare calculations and individuals can often smooth transitory shocks through own savings so that their welfare impact is limited. By contrast, “bad mobility”  $\sigma_\epsilon^2$  due to risk and “good” mobility due to convergence,  $\rho$ ) account for roughly 1 percent each across 1 year.<sup>22</sup>

---

<sup>21</sup>See Antman and McKenzie (2007) for a discussion of measurement error and mobility using this data.

<sup>22</sup>Note that since mobility is highly non-linear in its underlying parameters, measured mobility does not decompose additively into its component parts.

The relative impact of these parameters clearly changes as we increase the span over which we are measuring mobility. At 25 years, setting transitory shocks to zero reduces mobility by a still large, but much reduced 23 percent (as transitory shocks are, by definition, transitory and mobility over this duration is driven to a greater extent by the cumulative effect of persistent shocks experienced by individuals over this period). By contrast, mobility due to persistent risk accounts for 7.4 percent and mobility due to convergence accounts for 8.6 percent. Having identified which parameters have the largest influence on measured mobility, we now turn to their relative contribution to welfare.

## VI. Welfare Analysis

The voluminous literature on consumption and saving with individual income risk and incomplete insurance markets has generated a number of insights.<sup>23</sup> One important insight is that workers can effectively self-insure against transitory income shocks through borrowing or own saving, and that the effect of these shocks on equilibrium prices and quantities are relatively small.<sup>24</sup> A second important insight of this literature is that very persistent or fully permanent income shocks have substantial effects on consumption and welfare even if individual households have own savings, but no or only limited access to insurance markets. Indeed, when labor income is the main source of income and labor income shocks are highly persistent, we would expect that consumption responds (almost) one-for-one to labor income shocks. This point has been made more formally Constantinides and Duffie (1996) using dynamic general equilibrium exchange models with incomplete markets. Constantinides and Duffie (1996) only consider the case in which income follows a random walk ( $\rho = 1$ ), but Krebs (2007) also analyzes an extension with  $\rho < 1$  and costs of financial intermediation that introduce a spread between the borrowing rate and the lending rate. In this section, we discuss the main ideas and results of the model analyzed in Krebs (2007).

---

<sup>23</sup>See, for example, Heathcote, Storesletten, and Violante (2009) for a recent survey.

<sup>24</sup>See, for example Aiyagari (1994) and Heaton and Lucas (1996) for quantitative work and Levine and Zame (2002) for a theoretical argument. Kubler and Schmedders (2002) show that welfare cost of “transitory” labor income shocks are non-negligible, but the labor income process they consider has  $\rho = 0.5$ .

## VI.1. Consumption

The model features long-lived, risk-averse workers with homothetic preferences who make consumption/saving choices in the face of uninsurable income shocks. Workers' preferences over consumption plans,  $\{c_{it}\}$ , allow for a time-additive expected utility representation with one-period utility function of the CRRA-type, where in this paper we confine attention to the log-utility case (degree of relative risk aversion of 1):

$$U(\{c_{it}\}|\omega_{i0}) = E \left[ \sum_{t=0}^{\infty} \beta^t \ln c_{it} | \omega_{i0} \right]. \quad (9)$$

Workers maximize expected lifetime utility subject to a sequential budget constraint that allows them to transfer wealth across periods through saving (or borrowing). The model is an exchange economy with endogenous interest rate (general equilibrium).

In order to apply the equilibrium characterization result of Krebs (2007), we need to introduce three modification of the labor income process (1). First, we abstract from ex-ante heterogeneity and time-effects:  $\mu_t(x_{it}) = \mu$ . For simplicity, we set  $\mu = 0$  so that the mean of labor income (aggregate labor income) is normalized to one (see below). Second, measurement error should not enter into the worker's budget constraint, and the part of  $\eta$  that represents measurement error should therefore be omitted. Further, as we have argued before, the part of  $\eta$  that is due to true income shocks is expected to have only small effects on equilibrium consumption and welfare. To simplify the analysis, we neglect these small effects of transitory income shocks and set  $\ln y_{it} = \omega_{it}$ , where  $\{\omega_{it}\}$  is an AR(1) process as in the previous section. Third, the distribution of the innovation term,  $\epsilon$ , and the distribution of initial income,  $\omega_0$ , include a mean-adjustment:  $\epsilon \sim N(-\sigma_\epsilon^2/2, \sigma_\epsilon^2)$  and  $\omega_0 \sim N(-\sigma_{\omega_0}^2/2, \sigma_{\omega_0}^2)$ . This adjustment is necessary to ensure that  $\sigma_\epsilon^2$  and  $\sigma_{\omega_0}^2$  can be interpreted as uncertainty parameters (see below).<sup>25</sup>

---

<sup>25</sup>The main part of the analysis in Krebs (2007) deals with the random walk case, but the Appendix discusses the extension to labor income shocks that are not fully permanent. The labor income process specified in the Appendix of Krebs (2007) is equivalent to an AR(1) process with an innovation term that has finite support, which rules out the case of a normal distribution. One way to apply the results of Krebs (2007) to the present analysis is to truncate all normal distributions at an arbitrarily large point, and to think of all equilibrium results as approximate results for which the approximation error can be made arbitrarily small.

Our specification of the labor income process implies that

$$\begin{aligned}
 E[y_{i,t+1}|I_t] &= y_{it}^\rho & (10) \\
 var[y_{i,t+1}|I_t] &= e^{\sigma_\epsilon^2} - 1 \\
 E[y_{i0}] &= 1 \\
 var[y_0] &= e^{\sigma_{\omega_0}^2}
 \end{aligned}$$

where  $I_t$  denote the information available at time  $t$ . Thus, increases in either  $\sigma_\epsilon$  or  $\sigma_{\omega_0}$  increase the variance of labor income without any change in the (conditional) mean – they lead to a mean-preserving spread. In other words, the two parameters measure risk/uncertainty.<sup>26</sup>

If  $\rho = 1$  and labor income follows a random walk, then the equilibrium interest rate will adjust so that individual workers will optimally decide to set consumption equal to labor income (see Constantinides and Duffie (1996) and Krebs (2007) for details). If  $\rho$  is not equal to one, but not too far away from one, then a sufficiently large difference in the borrowing and lending rate (cost of financial intermediation) will ensure that in equilibrium households still choose to set consumption equals labor income (see the Appendix of Krebs (2007) for details). In short, in equilibrium we have  $c_{it} = y_{it}$ , that is, consumption and labor income move one-for-one.

## VI.2. Mobility and Welfare

Using  $c_{it} = y_{it} = \omega_{it}$  and the income specification discussed above, we can evaluate the expected lifetime utility (9) of an individual with initial income  $\omega_{i0}$ . Taking the expectation over  $\omega_{i0}$  yields social welfare,  $W$ , where we assume that each individual household is assigned equal weight in the social welfare function. In other words, social welfare is the expected lifetime utility from an *ex ante* point of view when the initial condition,  $\omega_0$ , is not yet known

---

<sup>26</sup>The  $n$ -period ahead variances,  $var[y_{i,t+n}|I_t]$ , in general depend on  $\sigma_\epsilon^2$  for  $n \geq 2$  if  $\rho < 1$ . We can correct for these “higher-order” effects without essentially changing the main results of the paper. More precisely, a modified version of the welfare formula (11), which adjusts for the change in mean income, yields quantitative results that are very close to the results reported here. Details are available on request.

(veil of ignorance). More formally, we have

$$\begin{aligned}
W &= E \left[ \sum_{t=0}^{\infty} \beta^t \ln c_{it} \right] \\
&= E \left[ E \left[ \sum_{t=0}^{\infty} \beta^t \ln c_{it} \middle| \omega_0 \right] \right] \\
&= E \left[ -\frac{\beta}{(1-\beta)(1-\beta\rho)} \frac{\sigma_{\epsilon}^2}{2} + \frac{1}{1-\beta\rho} \omega_0 \right] \\
&= -\frac{\beta}{(1-\beta)(1-\beta\rho)} \frac{\sigma_{\epsilon}^2}{2} - \frac{1}{1-\beta\rho} \frac{\sigma_{\omega_0}^2}{2}
\end{aligned} \tag{11}$$

The formula (11) shows how social welfare depends on the various income parameters and the preference parameter  $\beta$ . In particular, (11) shows that an increase in uncertainty, either about initial conditions or about future labor market conditions, will reduce social welfare. Further, an increase in  $\rho$  increases uncertainty about lifetime income, and therefore reduces welfare:

$$\frac{W}{\partial \sigma_{\omega_0}^2} < 0, \quad \frac{W}{\partial \sigma_{\epsilon}^2} < 0, \quad \frac{W}{\partial \rho} < 0 \tag{12}$$

In order to express welfare changes in economically meaningful units, we calculate the corresponding change in consumption in each period and possible future state that is necessary to compensate the worker for the change in uncertainty. For example, suppose we compare two economies, one with income parameters  $(\sigma_{\omega_0}^2, \sigma_{\epsilon}^2, \rho)$  and one with income parameters  $(\hat{\sigma}_{\omega_0}^2, \hat{\sigma}_{\epsilon}^2, \hat{\rho})$ . We then define the consumption-equivalent welfare change,  $\Delta$ , of moving from  $(\sigma_{\omega_0}^2, \sigma_{\epsilon}^2, \rho)$  to  $(\hat{\sigma}_{\omega_0}^2, \hat{\sigma}_{\epsilon}^2, \hat{\rho})$  as

$$E \left[ \sum_{t=0}^{\infty} \beta^t \ln (c_{it}(1 + \Delta)) \right] = E \left[ \sum_{t=0}^{\infty} \beta^t \ln \hat{c}_{it} \right], \tag{13}$$

where  $c$  is consumption in the first economy and  $\hat{c}$  is consumption in the second economy. Using the definition (13) and the welfare formula (11), we find:

$$\begin{aligned}
\ln(1 + \Delta) &= \frac{\beta}{(1-\beta\hat{\rho})} \frac{\hat{\sigma}_{\epsilon}^2}{2} + \frac{(1-\beta)}{(1-\beta\hat{\rho})} \frac{\hat{\sigma}_{\omega_0}^2}{2} \\
&\quad - \frac{\beta}{(1-\beta\rho)} \frac{\sigma_{\epsilon}^2}{2} - \frac{(1-\beta)}{1-\beta\rho} \frac{\sigma_{\omega_0}^2}{2}
\end{aligned} \tag{14}$$

As mentioned before, measurement error and transitory shocks have (almost) no effect on welfare. In contrast, the effect of the other two mobility parameters,  $\sigma_\epsilon$  and  $\rho$ , turn out to be quite substantial. For example, based on the welfare formula (14) and an annual discount factor of  $\beta = 0.96$ , a value that is standard in the macro-economic literature (for example, Cooley and Prescott, 1995), we find that removing all “bad mobility”,  $\sigma_\epsilon^2 = 0$ , leads to a welfare gain of about 12 percent of lifetime consumption. Using the same discount factor, the welfare cost of removing all “good mobility”,  $\rho = 1$ , is equal to 8 percent of lifetime consumption, again a significant welfare effect. Finally, removing both “good” and “bad” mobility at the same time,  $\sigma_\epsilon^2 = 0$  and  $\rho = 1$ , leads to a net welfare gain of about 10 percent of lifetime consumption. The last result shows that the welfare formula (14) is highly non-linear and that the positive welfare effect of catching-up,  $\rho < 1$ , is closely linked to the presence or absence of persistent income shocks,  $\epsilon$ . Calculations with other values of  $\beta$  yield similar results as indicated in Table 5.

In sum, the application of our general framework to Mexico provides striking results. The parameter that accounts for the largest part of measured mobility,  $\sigma_\eta$ , has (almost) no effect on welfare, and the two parameters that have large effects on welfare,  $\sigma_\epsilon$  and  $\rho$ , have only a modest contribution to measured mobility, and least over small time durations. Clearly, our welfare results depend on the choice of preference parameters, namely the degree of risk aversion and the degree of impatience (discounting). However, by using a logarithmic utility function we have already chosen a relatively low degree of (relative) risk aversion, namely one, and any increase in the degree of risk aversion would only increase the welfare effects. Further, lowering the discount factor  $\beta$  will lower the welfare effects, but for a wide range of values of  $\beta$  the welfare effects remain substantial and the ranking of the different parameters remains the same (see Table 5). In short, our welfare results are valid for a wide range of preference parameters.

## VII. Conclusions

This paper develops an analytically tractable framework linking individual income dynamics, social mobility and welfare. This analytical framework that we develop has the merit that the links between different determinants of income mobility and social welfare are drawn out in a simple and transparent manner – allowing for a clearer analytical and quantitative discussion of these interrelated concepts than has generally been possible in the past. In particular, we discuss in detail how different determinants of measured income mobility (shocks to income, and convergence forces, for instance) may have quite different implications for welfare. This implies that two societies with the same initial distribution of income and the same level of measured income mobility may be characterized by quite different levels of social welfare. Decomposing the determinants of mobility is thus shown to be crucial from the standpoint of welfare evaluation.

An important strength of the proposed framework is its empirical implementability. The quantitative evaluation of mobility and welfare in our context entails the estimation of income process parameters may be achieved using combined cross sectional and longitudinal data on individual incomes and relatively straightforward econometric techniques. The results from Mexico are striking. Most of measured mobility is estimated to be driven by transitory shocks to income and is therefore (almost) welfare neutral. Only a small part of mobility (i.e., mobility in permanent income) is driven by either social-welfare-reducing persistent income shocks or welfare-enhancing catching-up of low-income individuals with high-income individuals. Despite their small contributions to measured mobility, the implications for welfare are large. Decomposing mobility into its fundamental components is thus crucial from the standpoint of welfare evaluation.

Year and wave dummies		Yes		
N		782179		
R <sup>2</sup> Adj		0.595		

Note: Regression of log income on sex, age as a dummy variable, schooling, schooling square and a year time specific dummy and a dummy for whether the data correspond to the first period or the fifth. Data are pooled across all years. Based on the Mexican Monthly Urban Employment Survey, 1987-2003, using individuals between 20 and 65 years of age.

Table 3: Estimation of Mobility Parameters

	<i>Full Sample</i>	<i>Restricted</i>
$\rho$	0.977*** (0.0019)	0.976*** (0.0037)
$\sigma_\omega^2$	0.104*** (0.0038)	0.104*** (0.0068)
$\sigma_\epsilon^2$	0.015*** (0.0008)	0.016*** (0.0016)
$\sigma_\eta^2$	0.203*** (0.0039)	0.217*** (0.0073)
<i>Time Dummies</i>	Yes	Yes
<i>N</i>	387460	99570

Note: Estimation using Non-linear SUR estimation. Dependent variables: Eq 1 variance, Eq 2 covariance. Variance calculated as the square of the residual of the mincer regression. Covariance as the covariance of the residual in the first quarter observed with that of the fifth quarter.  $\rho$  represents the autoregressive coefficient or convergence parameter.  $\sigma_\omega^2$  represents the variance of the initial distribution of income.  $\sigma_\epsilon^2$  represents the variance of permanent shocks.  $\sigma_\eta^2$  represents the variance of the transitory or measurement error component of income. A complete and separate set of time dummies is included in each equation. Estimates using the Mexican Monthly Urban Employment Survey, 1987-2003, using individuals between 20 and 65 years of age. Column 1 uses all observations. Column 2 just those beginning Q1 of each year. Robust standard errors in parentheses. \*  $p < 0.1$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

Table 4: Mobility Analysis

	Span of measurement ( $t$ , in years)		
	1	10	25
Actual mobility	0.674	0.763	0.846
% $\Delta$ if:			
$\rho = 0$	-0.77	-5.2	-8.6
$\sigma_\epsilon^2 = 0$	-1.2	-6.6	-7.4
$\sigma_\eta^2 = 0$	-89.7	-45.7	-23.3

Note: Table shows the percentage decline in mobility as component parameters are individually set to zero relative to actual mobility calculated from equation (7) using parameters estimated in Table 3 based on the Mexican Monthly Urban Employment Survey, 1987-2003.  $\rho$  represents the autoregressive coefficient or convergence parameter.  $\sigma_\epsilon^2$  represents the variance of permanent shocks.  $\sigma_\eta^2$  represents the variance of the transitory or measurement error component of income. Mobility is calculated across a span,  $t$ , of 1, 10 and 25 years.

Table 5: Welfare Analysis

	$\sigma_\epsilon^2 = 0$	$\rho = 1$	$\sigma_\epsilon^2 = 0$ and $\rho = 1$
% $\Delta$ if:			
$\beta = 0.96$	12.56	-8.04	10.5
$\beta = 0.95$	10.64	-5.82	8.91
$\beta = 0.94$	9.21	-4.45	7.72
$\beta = 0.90$	5.87	-2.05	4.93

*Note:* Table shows the percentage change in welfare calculated measured as a percent of lifetime consumption as  $\sigma_\epsilon^2$ , the variance of permanent shocks, is set to 0 (no income risk) and  $\rho$ , the convergence parameter, is set to one (no convergence).  $\beta$  is the annual discount factor. Welfare is calculated using equations (11) and (14) and the estimated values in Table 3 using the Mexican Monthly Urban Employment Survey 1987-2003.
